Infectious Bovine Keratoconjunctivitis (IBK, "Pink eye", New Forest Disease”).

IBK is a highly contagious disease caused by a bacterium Moraxella bovis that can spread rapidly during the summer months.

It is more commonly seen in young stock than adults. Head and nuisance flies can act as mechanical vectors for *M. bovis* and dust can be a risk factor. The pain associated with this condition is more intense in strong sunlight.

Most eye lesions are selected for treatment on the basis of obvious tear-staining of the face which becomes increasingly purulent matting the lashes and hair of the face. There is marked pain when the eye is exposed to direct sunlight. The ocular lesions are very painful and disrupt grazing patterns causing poor performance and even weight loss. Bilateral lesions cause temporary blindness and the affected animals tend to wander aimlessly about.

- tear-staining of the face
- pus matting the lashes and hair of the face
- conjunctivitis
- corneal ulceration
- pain when the eye is exposed to direct sunlight

Spontaneous recovery may occur in mild cases three to five days after clinical signs are first observed, and is complete two weeks later. In severe cases, ulceration may progress to corneal perforation but this is uncommon.

The main differential diagnoses your veterinary practitioner will consider include

- foreign bodies (e.g. grass awns) within the conjunctival sac,
- bovine iritis
- infectious bovine rhinotracheitis (IBR).
Prompt treatment is essential. Topical ophthalmic antibiotic cream containing cloxacillin is commonly used. Antibiotic injection (penicillin, oxytetracycline or ceftiofur) into the dorsal bulbar conjunctiva is the best treatment but can be difficult to achieve in fractious cattle and requires good restraint. Injection into the upper palpebral conjunctiva is commonly used but it should be noted that this technique will not give residual antibiotic levels in the eye and relies on leakage onto the cornea from the injection site. This technique has no advantage over systemic injection except the much lower cost because of the smaller antibiotic dose.

When subconjunctival or topical treatment is not practical then single dose long acting oxytetracycline or florfenicol, have been reported to be effective but will prove more expensive.

In severe cases suturing the eyelids together using mattress sutures can be undertaken under local anaesthesia together with an auriculopalpebral block. The sutures must not contact the cornea and are removed after - two weeks. Temporary adhesive eye patches can also be used to provide protection from environmental conditions. Severely affected cattle should be housed with ready access to food and water.

Metaphylactic injection of all at-risk cattle with a single intramuscular injection of long-acting oxytetracycline could be considered in severe epidemics but there are no supporting field data.

**Management/Prevention/Control measures**

Outbreaks of IBK may occur after the introduction of purchased stock therefore, whenever possible, all new stock should be managed separately as one group away from the main herd. Fly control using ear tags and pour-on insecticides is never absolute and repeated treatments prove costly. Development of immunity following infection is variable.

- All new stock should be managed separately
- Fly control using ear tags and pour-on insecticides

**Bovine iritis (Syn: "silage eye")**

Bovine iritis, colloquially known as "silage eye" in the UK, is a common cause of uveitis in cattle of all ages fed winter rations of baled silage/haylage.

**Clinical presentation**

The initial presenting signs are excessive tear-staining, blinking and forced closure of the eyelids, and pain from direct sunlight. Within two to three days there is a bluish-white opacity of the surface of the eye (cornea). Regression of ocular lesions takes several weeks without treatment.
- excessive tear-staining, initially clear, becoming sticky and purulent
- blinking
- forced closure of the eyelids
- bluish-white opacity of the surface of the eye which can become yellow as pus develops
- Bulges in the iris, with white discolouration.
- Very painful particularly in direct sunlight

**Treatment**

There is a good response to combined subconjunctival injection of oxytetracycline and dexamethasone (2-3ml of 5 or 10% oxytetracycline mixed with 0.5-1ml soluble dexamethasone) in acute cases administered by the veterinary practitioner.

**Management/Prevention/Control measures**

Big-bale silage can be rolled out rather than placing in ring feeders to prevent cows burrowing their heads into the bale but this is impractical in most situations. Attention to detail when baling and wrapping silage and ensuring appropriate fermentation conditions should limit contamination with *L. monocytogenes* the cause of this problem. However, exposure to air for several days before the large bale is eventually eaten provides an ideal environment for *L. monocytogenes* multiplication.

**Ocular Squamous Cell Carcinoma (Syn: "Cancer eye")**

**Definition/Overview**

Ocular squamous cell carcinomas are uncommon in northern Europe. They typically arise from the third eyelid or conjunctival membrane of the lower eyelid following exposure to prolonged ultraviolet radiation (sunlight).

**Clinical presentation**

Initially there is closure of the eyelids and ocular discharge caused by mechanical irritation of the eye's surface.

**Treatment**

Early cases involving the third eyelid can be treated with surgical excision under local anaesthesia or with cryosurgery.

Enucleation, under standing xylazine sedation and retrobulbar block, may be required in advanced
cases involving the limbus but may not be an option for commercial value cattle which must be culled for welfare reasons.

**Management/Prevention/Control measures**

Select cattle with pigmented skin surrounding the eyelids.
