**Johne's Disease (Paratuberculosis)**

Johne's disease is greatly under-diagnosed in many UK sheep flocks. The disease is characterised by emaciation but not, as in cattle, chronic severe diarrhoea. Disease is encountered in all sheep husbandry systems including extensively-managed flocks. In many infected flocks the annual ewe mortality rate from Johne's disease is estimated to be as high as 5 to 10 per cent.

Clinical Presentation

Johne's disease presents as chronic weight loss with poor fleece in individual middle-aged (typically 3 to 4 years-old) sheep with normal dentition and fed an appropriate plane of nutrition.

*Chronic diarrhoea, unlike cattle, is not a feature in sheep affected by paratuberculosis.*
Diarrhoea may occur in sheep with Johne's disease because of concurrent parasitic gastroenteritis. Emaciated sheep are typically detected during routine flock handling procedures, such as pre-mating checks, when their body condition score of 1.5 or below (scale 1 to 5) compares unfavourably to other sheep managed in a similar way with scores of 3.0 or greater. Chronic diarrhoea, unlike cattle, is not a feature in the majority of sheep affected by paratuberculosis and sheep often void pelleted faeces, unless there is also a heavy concurrent parasitic burden. Affected sheep appear bright and alert with a normal appetite but rumen fill is reduced, with consequent sunken sublumbar fossae. The wool is poor quality and the fleece appears more open than usual. During the agonal stages affected sheep may become recumbent and too weak to stand. Submandibular oedema (bottle jaw) presents only in extreme cases. The severity of Johne's disease is compounded by concurrent parasitism, especially fasciolosis.

During the agonal stages affected sheep may be too weak to stand.

Lambs born to ewes in the terminal stages of Johne's disease have low birthweights.

**Differential diagnoses**

In order of decreasing importance, the common causes of weight loss are:

**Group problem:**
- Poor flock nutrition
- Fasciolosis
- Chronic parasitism due to poor pasture management and erroneous control strategies
- Chronic parasitism caused by anthelmintic-resistant strains of nematodes
- Virulent footrot

**Individual sheep:**
- Poor dentition especially molar teeth
- Chronic pneumonia, mastitis, or other septic focus
- Chronic severe lameness
- Ovine pulmonary adenocarcinoma
- Intestinal adenocarcinoma

**Diagnosis**

The intestinal changes caused by Johne's disease cannot reliably be diagnosed by an on-farm necropsy even when undertaken by experts. More importantly, a single necropsy provides little information regarding the prevalence of certain disease conditions on the farm.

Lambs born to ewes in the terminal stages of disease have low birthweights.
Marked thickening of the gut wall (lower necropsy sample; top normal) may not always be so obvious as this example.

In most situations it will prove more useful to investigate weight loss in 10 or more ewes than to send a single ewe for detailed post mortem examination. Serum albumin and globulin determinations provide your veterinary surgeon with the most useful screening tests for the investigation of chronic weight loss in a number of adult sheep.

Sheep with Johne's disease have profound hypoalbuminaemia and a normal globulin concentration. These changes result from loss of albumin across the damaged gut.

It must be remembered that sheep with Johne's co-incidentally often have very high parasitic faecal egg counts indeed and such results may lead to erroneous conclusions. Sheep with Johne's disease also cause very considerable pasture contamination due to this very high egg production.

Significant serological titres (either AGID or ELISA) are only detected in approximately 60 per cent of clinical paratuberculosis cases resulting in a high false negative rate (low sensitivity) although the specificity is high (greater than 95%).

Direct faecal examination provides unreliable results as there may be few bacteria present.

Cultural isolation taking at least eight weeks, and possibly up to six months, has very limited practical application.

**Sponsor Content**

**Necropsy**

There is an emaciated carcass with gelatinous atrophy of fat depots. Thickening of the ileum with prominent ridging is not always obvious in Johne's disease but the mesenteric lymph nodes are often visibly enlarged. The diagnosis is confirmed after ZN staining of ileal sections and ileo-caecal lymph nodes which demonstrate clumps of acid-fast bacteria.

There is an emaciated carcass with gelatinous atrophy of fat depots.

**Management / Prevention / Control measures**

The true Johne's disease incidence in UK sheep flocks remains unknown but many flocks have losses in excess of 5 per cent without appreciating the cause of such losses.

Encouraging results with much reduced disease prevalence have been reported following adoption of a vaccination programme in several countries.

Vaccination offers the best long term prospect for control of Johne's disease in sheep flocks (approximately £2-3 per dose).

**Economics**

Difficulties with confirmation of the provisional diagnosis of Johne's disease, coupled with very few ewes culled for poor condition/emaciation submitted to the veterinary surgeon, lead to a gross underestimation of the prevalence and financial impact of this disease in the UK.

**Intestinal adenocarcinoma**

Intestinal adenocarcinoma is a sporadic tumour of the small intestine causing weight loss and emaciation in adult sheep.

**Clinical Presentation**

The affected adult sheep presents in much poorer condition than other sheep in the group. While fluid accumulation in the abdomen is present in most cases, it may prove difficult to assess on clinical examination. Veterinary ultrasound examination provides a quick and reliable assessment of the amount of peritoneal fluid.
Fluid accumulation in the abdomen is present in most cases of intestinal adenocarcinoma (sheep on right).

**Treatment**
There is no recognised treatment and affected sheep should be euthanased when all other treatable alternative conditions have been excluded by your veterinary surgeon.

Sheep with septic peritonitis are dull, depressed, and anorexic.

**Differential diagnoses**
Your veterinary surgeon will also consider:
- Septic peritonitis most frequently follows dystocia/uterine tears therefore the most common differential diagnosis is infection of the womb.
- Retained foetus could present with similar signs to peritonitis.
- Hypocalcaemia presents as a dull, recumbent sheep with bloat which could be confused with peritonitis at initial presentation.
- Sub-acute fasciolosis may result in focal peritonitis involving the liver.

**Treatment**
Antibiotic therapy is hopeless and is often only undertaken in the event that the diagnosis is incorrect and the sheep is suffering from metritis or another infectious disease.

**Abomasal emptying defect**
Abomasal emptying defect is an uncommon, yet probably under-diagnosed, disorder reported most frequently in pedigree Suffolk sheep but also occurs in other breeds and crossbreeds. The cause remains unknown but its recognition primarily in Suffolk sheep may suggest an hereditary component.
Signs of abomasal emptying defect develop over some months with weight loss and abdominal distension especially on the lower right side.

Clinical presentation
Signs develop over some months with weight loss progressing to emaciation. There is increasing abdominal distension especially on the lower right side when the sheep in viewed from behind.

Differential Diagnoses
Abomasal impaction should be distinguished from peritonitis and adenocarcinoma which may result in accumulations of excess peritoneal fluid.
Poor cheek teeth with inadequate mastication of fibrous foods may result in rumen distension.
The diagnosis is confirmed at necropsy.

The diagnosis of abomasal emptying defect is confirmed at necropsy.

Treatment
There is no recognised treatment and affected sheep should be euthanased when all other treatable alternative conditions have been excluded.

Management / Prevention / Control measures
There are presently no control measures. In pedigree flocks because of the likely hereditary nature of this disorder, it would be prudent to cull progeny from sheep which developed this condition and their progeny.
